#### Abstract

We present an analytic model for virtual pion Compton scattering. Using factorization of the Regge residues we predict the scale-invariant electroproduction structure functions for $\mathrm{e}^{-} \pi \rightarrow \mathrm{e}^{-} \mathrm{X}$, and obtain results for the pion form factor that compare well with the data. By fitting recent data from CEA and the SLAC-LBL-SPEAR collaboration for the ratio $R=\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons $) / \sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mu^{+} \mu^{-}\right)$, and for the mean multiplicity of charged pions, we obtain predictions for the inclusive process $\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \pi^{-} \mathbf{X}$. In particular, the predicted $E_{\pi} \mathrm{d}^{3} \sigma / \mathrm{d} p^{3}$ for the inclusive process $\mathrm{e}^{+} \mathrm{e}^{--} \rightarrow \pi^{-} \mathrm{X}$ shows a strong diffractive type of behaviour with a slope for $\sqrt{ } q^{2} \sim 4.8 \mathrm{GeV}$ approximately the same as in $\mathrm{pp} \rightarrow \pi^{-} \mathrm{X}$. The ratio $R$ is predicted to rise linearly versus $\sqrt{ } q^{2}$ until some high energy, beyond which it tends to a constant, while the multiplicity remains essentially constant. The mechanism in the model that produces these predictions is the build-up or "statistical bootstrapping" of meson resonances in the direct (or missing mass) s-channel.

## 1. Introduction

Recent experiments [1,2] have revealed that up to a total c.m. energy of 5 GeV , the total cross section for the process $\mathrm{e}^{+}+\mathrm{e}^{-} \rightarrow$ hadrons may be falling more slowly with increasing energy than $\sigma_{\mu^{+} \mu^{-}}$, the point-like cross section for $\mathrm{e}^{+}+\mathrm{e}^{-} \rightarrow \mu^{+}+\mu^{-}$. This behaviour is already in conflict with the generalized vector dominance model [3], which predicts that $R\left(q^{2}\right) \equiv \sigma_{\text {tot }}\left(q^{2}\right) / \sigma_{\mu^{+} \mu^{-}}-\left(q^{2}\right) \sim$ const. for moderate values of $q^{2}$, as is required to explain the early onset of scale invariance of the nucleon electroproduction structure function.

Furthermore, the new data have inspired a reexamination of the parton (or quark) models [4] which, in their simplest forms, predict that $R\left(q^{2}\right) \sim$ const. for asymptotic values of $q^{2}$. It has been suggested [5] that the annihilation data have not yet reached their scale-invariant limit, so that the simple parton model is not

[^0]valid at $q^{2}=25 \mathrm{GeV}^{2}$, and requires modification for finite $q^{2}$. Of course, we are still left with the fundamental question of why the quarks or partons have not yet been observed.

In this paper, we study electron-positron annihilation into pions by extending a model for the nucleon Compton amplitude [6] to the case of pion Compton scattering. The model satisfies the following fundamental requirements: (a) Mandelstam analyticity, (b) crossing symmetry, (c) scale invariance in the limit $\left|q^{2}\right| \rightarrow \infty$, (d) Regge behaviour in all channels, (e) resonance poles in the unphysical sheet, (f) generalized vector meson dominance (i.e. the model contains cuts in $q^{2}$ as well as poles in the second sheet of the $q^{2}$ plane), (g) $\mathrm{SU}(3)$ structure of the currents.

In sect. 2, crossing symmetry and isospin invariance are used to obtain the form of the amplitude, and a model analogous to the nucleon Compton amplitude in ref. [6] is obtained. The analytically continued form of the amplitude is derived in the annihilation region. We implement factorization of the pomeron and $\mathrm{P}^{\prime}$ residues in the Regge limit in sect. 3. By requiring that the threshold behaviour of the scaleinvariant electroproduction structure function be smooth in our model, a prediction is obtained for the structure function. The pion form factor is then predicted with the help of the Bloom-Gilman sum rule [7-8] and compared with recent data. In sect. 4, we formulate inclusive sum rules to obtain the total cross section and mean multiplicity of pions produced in $\mathrm{e}^{+} \mathrm{e}^{-}$annihilation in terms of the cross section for $\mathrm{e}^{+}+\mathrm{e}^{-} \rightarrow \pi+\mathrm{X}$. In sect. 5, we discuss the results obtained from fitting the total cross section and mean multiplicity. With the scale invariance breaking behaviour of the model thus determined, we are able to make predictions for the annihilation structure function, and the inclusive pion production cross sections for finite values of $q^{2}$. In sect. 6 , we end with some concluding remarks about our results.

## 2. Analytic model

Following ref. [6], we define the double helicity-flip amplitude for pion Compton scattering by

$$
\begin{equation*}
T_{2}^{\pi}\left(s, t, q_{1}^{2}, q_{2}^{2}\right)=-\left(q_{1} \cdot q_{2}\right) A\left(s, t, q_{1}^{2}, q_{2}^{2}\right)+B\left(s, t, q_{1}^{2}, q_{2}^{2}\right) \tag{2.1}
\end{equation*}
$$

where we assume that $A$ satisfies a Mandelstam representation and $B$ is the Born term. The amplitude $A$ can be written as a sum of contributions from isovector ( $i=3$ ) and isoscalar $(i=8)$ photons

$$
\begin{equation*}
A=A_{33}+\frac{1}{\sqrt{3}} A_{38}+\frac{1}{\sqrt{3}} A_{83}+\frac{1}{3} A_{88} \tag{2.2}
\end{equation*}
$$

The amplitudes $A_{i j}$ may be decomposed into amplitudes of definite isospin $I$, denoted by $A_{i j}^{I}$. We write

$$
\begin{equation*}
A_{i j}^{I}=F_{i j}^{I}+P_{i j}^{I} \tag{2.3}
\end{equation*}
$$

where $F$ is the non-diffractive contribution and $P$ is the pomeron contribution.
For the isovector-isovector amplitude $A_{33}$, we require that the exotic $I=2$ amplitudes must contain no $s, t$ and $u$ poles in the $s, t$ and $u$ channels, respectively. For example, in the $s$-channel:

$$
\begin{equation*}
F_{33}^{2}(s, t, u)=F^{33}(u, t) \tag{2.4}
\end{equation*}
$$

This function $F^{33}(x, y)$ has poles in both $x$ and $y$, but is not symmetric in these variables. Thus $F^{33}(s, t)$ has resonances lying on the exchange-degenerate $\rho-\mathbf{P}^{\prime}-$ $\mathbf{A}_{2}-\omega$ trajectory in the $s$ - and $t$-channels (we have omitted $q_{1}^{2}$ and $q_{2}^{2}$ for convenience). We further require that no pole occur more than once in the amplitudes. To satisfy these assumptions and $s-u$ crossing symmetry we are led, using crossing relations, to the following form:

$$
\begin{align*}
& F_{33}^{1}(s, t, u)=F^{33}(s, t)  \tag{2.5}\\
& F_{33}^{0}(s, t, u)=-\frac{1}{2} F^{33}(u, t)+\frac{3}{2} F^{33}(s, t) \tag{2.6}
\end{align*}
$$

To discuss the pomeron amplitude, we introduce the function $A_{\mathrm{P}}(t, s)$ which has a pomeron exchanged in the $t$-channel and no $s$-channel resonances. By requiring that the pomeron be exchanged only in the $t$-channel and that the Pomeranchuk theorem be satisfied, we obtain

$$
\begin{equation*}
P_{33}^{2}(s, t, u)=P_{33}^{1}(s, t, u)=P_{33}^{0}(s, t, u)=A_{\mathrm{P}}^{33}(t, s)+A_{\mathrm{P}}^{33}(t, u) . \tag{2.7}
\end{equation*}
$$

For $A_{88}$, we have that

$$
\begin{align*}
& F_{88}^{1}(s, t, u)=F^{88}(s, t)+F^{88}(u, t)  \tag{2.8}\\
& P_{88}^{1}(s, t, u)=A_{\mathrm{P}}^{88}(t, s)+A_{\mathrm{P}}^{88}(t, u) \tag{2.9}
\end{align*}
$$

Neither the pomeron nor any of the leading non-diffractive $t$-channel exchanges can contribute to the amplitudes $A_{38}$ and $A_{83}$. Although the $s$-channel exchanges cannot be ruled out so easily, we have investigated the effects of "non-diagonal" terms, such as $A_{38}$, and find that their inclusion does not alter our results.

The various pion Compton amplitudes are now given by

$$
\begin{align*}
A\left(\pi^{ \pm} \gamma \rightarrow \pi^{ \pm} \gamma\right)= & \frac{1}{2}\left(A_{33}^{1}+A_{33}^{2}\right)+\frac{1}{3} A_{88}^{1} \\
= & \frac{1}{2}\left(F^{33}(s, t)+F^{33}(u, t)\right)+A_{\mathrm{P}}^{33}(t, s)+A_{\mathrm{P}}^{33}(t, u) \\
& +\frac{1}{3}\left(F^{88}(s, t)+F^{88}(u, t)+A_{\mathrm{P}}^{88}(t, s)+A_{\mathrm{P}}^{88}(t, u)\right), \tag{2.10}
\end{align*}
$$

$$
\begin{aligned}
A\left(\pi^{0} \gamma \rightarrow \pi^{0} \gamma\right) & =\frac{1}{3} A_{33}^{0}+\frac{2}{3} A_{33}^{2}+\frac{1}{3} A_{88}^{1} \\
& =A\left(\pi^{ \pm} \gamma \rightarrow \pi^{ \pm} \gamma\right)
\end{aligned}
$$

The construction of the pomeron and non-diffractive amplitudes is analogous to the nucleon-photon case, discussed in ref. [6]. We have

$$
\begin{align*}
& A_{\mathrm{P}}^{i i}\left(t, s, q_{1}^{2}, q_{2}^{2}\right)=\gamma_{\mathrm{P}}^{i \ddot{i}}(t) \ln \left[1+\left(1-\omega^{\prime}\right)^{\frac{1}{2}}\right] \\
& \times w_{\mathrm{P}}\left(\omega^{\prime}\right)^{\alpha \mathrm{P}(t)-2} \mathcal{F}\left(q_{1}^{2}, q_{2}^{2}\right) D_{i}\left(q_{1}^{2}\right) D_{i}\left(q_{2}^{2}\right), \quad(i=3,8),  \tag{2.12}\\
& F^{i i}\left(s, t, q_{1}^{2}, q_{2}^{2}\right)=-\left[\gamma^{i i}\left(\omega^{\prime}\right) \Gamma\left(1-\alpha_{\rho}(s)\right) w_{\rho}(t)^{\alpha_{\rho}(s)}\right. \\
& \left.+\gamma_{\mathrm{P}^{\prime}}^{i i}(t) \Gamma\left(2-\alpha_{\rho}(t)\right) w_{\mathrm{P}^{\prime}}\left(\omega^{\prime}\right)^{\alpha_{\rho}(t)-2} \mathcal{F}\left(q_{1}^{2}, q_{2}^{2}\right)\right] \\
& \times D_{i}\left(q_{1}^{2}\right) D_{i}\left(q_{2}^{2}\right)+\Sigma(\text { satellites }), \quad(i=3,8) . \tag{2.13}
\end{align*}
$$

Here, the variable $\omega^{\prime}$ is defined by

$$
\begin{equation*}
\omega^{\prime}=1+x_{1} x_{2}\left(s-s_{t}\right), \tag{2.14}
\end{equation*}
$$

where

$$
\begin{equation*}
x_{i}=\left[a+\left(q_{t}^{2}-q_{i}^{2}\right)^{\frac{1}{2}}\right]^{-1}, \quad(i=1,2) . \tag{2.15}
\end{equation*}
$$

The elastic threshold is given by

$$
\begin{equation*}
s_{t}=4 m_{\pi}^{2} \tag{2.16}
\end{equation*}
$$

whereas $q_{t}$ and $a$ are given by

$$
\begin{equation*}
q_{t}=0.99 \mathrm{GeV} / c, \quad a=0.12 \mathrm{GeV} / c \tag{2.17}
\end{equation*}
$$

The vector meson propagators $D_{3}\left(q^{2}\right)$ and $D_{8}\left(q^{2}\right)$ are the same as in ref. [6], and the $\mathcal{F}$ function is given by

$$
\begin{equation*}
\mathscr{F}\left(q_{1}^{2}, q_{2}^{2}\right)=1+f\left(q_{1}^{2}\right) f\left(q_{2}^{2}\right), \tag{2.18}
\end{equation*}
$$

where

$$
\begin{equation*}
f\left(q^{2}\right)=\frac{c q^{2}\left(m_{\omega}^{2}-q^{2}\right)}{\left[a+\left(q_{t}^{2}-q^{2}\right)^{\frac{1}{2}}\right]^{n}}, \tag{2.19}
\end{equation*}
$$

with $c=4.1(\mathrm{GeV} / c)^{2}$ and $n=6$.

The $w$ functions are given by

$$
\begin{align*}
& w_{\mathrm{P}}\left(\omega^{\prime}\right)=A_{\mathrm{P}}+B_{\mathrm{P}} \omega^{\prime}+C_{\mathrm{P}}\left(1-\omega^{\prime}\right)^{\frac{1}{2}} \\
& w_{\mathrm{P}^{\prime}}\left(\omega^{\prime}\right)=A_{\mathrm{P}^{\prime}}+B_{\mathrm{P}^{\prime}} \omega^{\prime}+C_{\mathrm{P}^{\prime}}\left(1-\omega^{\prime}\right)^{\frac{1}{2}} \tag{2.20}
\end{align*}
$$

and, to ensure analyticity in $s$, the constants satisfy the conditions

$$
\begin{align*}
& A_{i}>0, \quad B_{i}<0, \quad C_{i}>0, \\
& 0 \leqslant C_{i}^{2}+4 B_{i}\left(A_{i}+B_{i}\right) \leqslant C_{i}^{2} \tag{2.21}
\end{align*} \quad\left(i=\mathrm{P}, \mathrm{P}^{\prime}\right)
$$

As in ref. [6], we take $B_{\mathrm{P}}=B_{\mathrm{P}^{\prime}}=-1$, although the values of $A_{\mathrm{P}}, A_{\mathrm{P}^{\prime}}, C_{\mathrm{P}}$ and $C_{\mathrm{P}^{\prime}}$ may differ from the nucleon scattering case. For the $t$-dependent $w$ function, we require for simplicity that $w_{\rho}(0)=1$.

The pomeron and $\mathrm{P}^{\prime}$ trajectories are the same as in ref. [6]; in particular, $\alpha_{\mathrm{P}}(0)=1$ and $\alpha_{P^{\prime}}(0)=\frac{1}{2}$. The $t$-channel residue functions are real-analytic functions of $t$, similar to those in the $\gamma \mathrm{N}$ scattering case. For the $s$-channel residue, we adopt the form

$$
\begin{equation*}
\gamma^{i i}\left(\omega^{\prime}\right)=\frac{k \gamma_{P^{\prime}}^{i i} \exp \left(-g\left(\omega^{\prime}\right)\right)}{\Gamma\left(n-\alpha_{\rho}(s)\right)\left[1+\left(s_{t}-s\right)^{\frac{1}{2}} / \Lambda\right]^{m}} \tag{2.22}
\end{equation*}
$$

where $k, \Lambda, n, m$ are constants. Also, $g\left(\omega^{\prime}\right)$ is a real analytic function:

$$
\begin{equation*}
g\left(\omega^{\prime}\right)=\frac{g_{1}\left(2-\omega^{\prime}\right)+g_{2}\left(2-\omega^{\prime}\right)^{2}}{\left[1+\left(\left(1-\omega^{\prime}\right) / \Delta\right)^{\frac{1}{2}}\right]^{4}} \tag{2.23}
\end{equation*}
$$

where $g_{1}, g_{2}$ and $\Delta$ are constants. Moreover,

$$
\begin{equation*}
\omega^{\prime}=1+\frac{s-s_{t}}{\left[a+\left(s_{t}-q_{1}^{2}\right)^{\frac{1}{2}}\right]\left[a+\left(s_{t}-q_{2}^{2}\right)^{\frac{1}{2}}\right]} \tag{2.24}
\end{equation*}
$$

The function $\gamma^{i i}\left(s, q_{1}^{2}, q_{2}^{2}\right)$ is analytic in the physical $s, q_{1}^{2}$ and $q_{2}^{2}$ sheets, except for normal-threshold cuts. In the limit $s \rightarrow \infty$, we have

$$
\begin{equation*}
\gamma^{i i}\left(s, q_{1}^{2}, q_{2}^{2}\right)=\mathrm{O}\left(s^{-\frac{1}{2} m}\right) \tag{2.25}
\end{equation*}
$$

where $m, \Lambda$ and $\Delta$ are chosen large and positive.
From (2.13) and (2.22) we find that for large $s$ :

$$
\begin{equation*}
\frac{\Gamma\left(1-\alpha_{\rho}(s)\right)}{\Gamma\left(n-\alpha_{\rho}(s)\right)} \approx(-s)^{1-n}, \tag{2.26}
\end{equation*}
$$

and we see from (2.25) that the direct channel resonance terms ultimately vanish for $s \rightarrow \infty$, because $\alpha( \pm \infty)=-$ const. (this will happen at very large $s$ values).

In the kinematic region where the direct channel resonance terms may be neglected, the structure functions for inelastic electroproduction off pions are given by

$$
\begin{equation*}
\nu W_{2}^{\pi}\left(\nu, q^{2}\right)=\nu W_{2}^{\mathrm{P}}\left(\nu, q^{2}\right)+\nu W_{2}^{\mathrm{P}^{\prime}}\left(\nu, q^{2}\right), \tag{2.27}
\end{equation*}
$$

where we have included only the dominant $P$ and $P^{\prime}$ exchanges, and

$$
\begin{align*}
& \nu W_{2}^{\mathrm{P}}\left(\nu, q^{2}\right)=\frac{-q^{2} \nu}{\pi} \mathcal{F}\left(q^{2}, q^{2}\right)\left[\gamma_{\mathrm{P}}^{33}\left[D_{3}\left(q^{2}\right)\right]^{2}+\frac{1}{3} \gamma_{\mathrm{P}}^{88}\left[D_{8}\left(q^{2}\right)\right]^{2}\right] \\
& \quad \times\left\{\frac{1}{2} \ln \left(\omega^{\prime}\right) \sin \phi_{\mathrm{P}}\left(\omega^{\prime}\right)-\tan ^{-1}\left[\left(\omega^{\prime}-1\right)^{\frac{1}{2}}\right] \cos \phi_{\mathrm{P}}\left(\omega^{\prime}\right)\right\}\left|w_{\mathrm{P}}\left(\omega^{\prime}\right)\right|^{-1},  \tag{2.28}\\
& \nu W_{2}^{\mathrm{P}^{\prime}}\left(\nu, q^{2}\right)=\frac{q^{2} \nu \Gamma\left(\frac{3}{2}\right)}{\pi} \mathcal{F}\left(q^{2}, q^{2}\right)\left[\frac{1}{2} \gamma_{\mathbf{P}^{\prime}}^{33}\left[D_{3}\left(q^{2}\right)\right]^{2}\right. \\
& \left.\quad+\frac{1}{3} \gamma_{\mathrm{P}^{\prime}}^{88}\left[D_{8}\left(q^{2}\right)\right]^{2}\right] \sin \left(\frac{3}{2} \phi_{\mathbf{P}^{\prime}}\left(\omega^{\prime}\right)\right)\left|w_{\mathbf{P}^{\prime}}\left(\omega^{\prime}\right)\right|^{-\frac{3}{2}} . \tag{2.29}
\end{align*}
$$

Here, we have neglected the satellite terms in (2.13) and defined $\nu \equiv(s-u) / 4 m_{\pi}$, and

$$
\begin{equation*}
\phi_{i}\left(\omega^{\prime}\right)=\tan ^{-1}\left(\frac{C_{i}\left(\omega^{\prime}-1\right)^{\frac{1}{2}}}{A_{i}+B_{i} \omega^{\prime}}\right), \quad\left(i=\mathrm{P}, \mathrm{P}^{\prime}\right) \tag{2.30}
\end{equation*}
$$

In the scale invariance limit $-q^{2} \rightarrow \infty, \omega \equiv-2 m_{\pi} \nu / q^{2}$ fixed, we have

$$
\begin{equation*}
\nu W_{2}^{\pi}\left(\nu, q^{2}\right) \rightarrow F_{2}^{\pi}(\omega)=F_{2}^{\mathbf{P}}(\omega)+F_{2}^{\mathbf{P}^{\prime}}(\omega) \tag{2.31}
\end{equation*}
$$

where

$$
\begin{align*}
& F_{2}^{\mathbf{P}}(\omega)=\gamma_{\mathrm{P}} \omega\left\{\frac{1}{2} \ln (\omega) \sin \phi_{\mathrm{P}}(\omega)-\tan ^{-1}\left[(\omega-1)^{\frac{1}{2}}\right] \cos \phi_{\mathrm{P}}(\omega)\right\}\left|w_{\mathrm{P}}(\omega)\right|^{-1},  \tag{2.32}\\
& F_{2}^{\mathrm{P}^{\prime}}(\omega)=-\gamma_{\mathbf{P}^{\prime}} \omega \sin \left(\frac{3}{2} \phi_{\mathrm{P}^{\prime}}(\omega)\right)\left|w_{\mathrm{P}^{\prime}}(\omega)\right|^{-\frac{3}{2}} \tag{2.33}
\end{align*}
$$

We have defined

$$
\begin{equation*}
\gamma_{P}=\frac{\gamma_{P}^{33}+\frac{1}{3} \gamma_{P}^{88}}{2 \pi m_{\pi}}, \quad \gamma_{P^{\prime}}=\frac{\Gamma\left(\frac{3}{2}\right)}{2 \pi m_{\pi}}\left(\frac{1}{2} \gamma_{P^{\prime}}^{33}+\frac{1}{3} \gamma_{P^{\prime}}^{88}\right) \tag{2.34}
\end{equation*}
$$

To obtain the structure function $W_{1}^{\pi}$, we assume that the Callan-Gross relation holds:

$$
\begin{equation*}
W_{1}^{\pi}\left(\nu, q^{2}\right)=\left(-\nu^{2} / q^{2}\right) W_{2}^{\pi}\left(\nu, q^{2}\right) \tag{2.35}
\end{equation*}
$$

To treat electron-positron annihilation, we write the cross section for $\mathrm{e}^{+}(k)+\mathrm{e}^{-}\left(k^{\prime}\right) \rightarrow \pi(p)+$ hadrons in terms of the annihilation structure functions $\bar{W}_{1}^{\pi}$ and $\bar{W}_{2}^{\pi}$ :

$$
\begin{align*}
& \frac{\mathrm{d}^{2} \sigma}{\mathrm{~d} \Omega \mathrm{~d} E_{\pi}}=\left(\frac{2 \alpha^{2}}{q^{4}}\right)\left(\frac{m^{2} \nu}{\sqrt{q^{2}}}\right)\left(1-\frac{q^{2}}{\nu^{2}}\right)^{\frac{1}{2}} \\
& \quad \times\left[2 \bar{W}_{1}^{\pi}\left(\nu, q^{2}\right)+\frac{2 m_{\pi}^{\nu}}{q^{2}}\left(1-\frac{q^{2}}{\nu^{2}}\right) \frac{\nu \bar{W}_{2}^{\pi}\left(\nu, q^{2}\right)}{2 m_{\pi}} \sin ^{2} \theta\right], \tag{2.36}
\end{align*}
$$

where $q=k+k^{\prime}, \nu=p \cdot q / m_{\pi}, \theta$ is the barycentric frame scattering angle and $E_{\pi}$ is the energy of the detected pion.

Our model has the virtue that, because it is analytic in $s, q_{1}^{2}$ and $q_{2}^{2}$, it may be continued to the annihilation region by using the method described in II:

$$
\begin{align*}
& 2 \pi i \bar{W}_{2}^{\pi}\left(\nu, q^{2}\right)=T_{2}^{\pi}\left(s+i \epsilon, 0, q^{2}+i \epsilon^{\prime}, q^{2}-i \epsilon^{\prime \prime}\right) \\
& -T_{2}^{\pi}\left(s-i \epsilon, 0, q^{2}+i \epsilon^{\prime}, q^{2}-i \epsilon^{\prime \prime}\right) \tag{2.37}
\end{align*}
$$

Here, $s$ is given by

$$
\begin{equation*}
s=(-p+q)^{2}=m_{\pi}^{2}+q^{2}-2 m_{\pi} \nu \geqslant m_{\pi}^{2} . \tag{2.38}
\end{equation*}
$$

By evaluating the discontinuity in (2.37), we get

$$
\begin{equation*}
\nu \bar{W}_{2}^{\pi}\left(\nu, q^{2}\right)=\nu \bar{W}_{2}^{\mathrm{P}}\left(\nu, q^{2}\right)+\nu \bar{W}_{2}^{\mathrm{P}^{\prime}}\left(\nu, q^{2}\right)+\bar{R}\left(\nu, q^{2}\right), \tag{2.39}
\end{equation*}
$$

where $\nu \bar{W}_{2}^{\mathrm{P}}$ and $\nu \bar{W}_{2}^{\mathrm{P}^{\prime}}$ are given by the right-hand sides of (2.28) and (2.29), respectively, and $\bar{R}$ is the contribution from the direct channel resonance term in (2.13). It is understood that, in (2.37), $q_{1}^{2}$ and $q_{2}^{2}$ are continued above and below their respective cuts, so that in (2.39) [6]:

$$
\begin{align*}
& \omega^{\prime}=1+\frac{s-s_{t}}{a^{2}+q^{2}-q_{t}^{2}},  \tag{2.40}\\
& \mathscr{F}\left(q^{2}, q^{2}\right)=1+\frac{c^{2} q^{4}\left(m_{\omega}^{2}-q^{2}\right)^{2}}{\left(a^{2}+q^{2}-q_{t}^{2}\right)^{6}}, \tag{2.41}
\end{align*}
$$

$$
\begin{equation*}
\left[D_{3}\left(q^{2}\right)\right]^{2}=\left[\left(q^{2}-m_{\rho}^{2}\right)^{2}+\Gamma_{3}^{2}\left(q^{2}-4 m_{\pi}^{2}\right)\right]^{-1} \tag{2.42}
\end{equation*}
$$

The resonance term $\bar{R}$ is given by

$$
\begin{align*}
& \bar{R}\left(\nu, q^{2}\right)=\frac{q^{2} \nu}{\pi} \operatorname{Im}\left\{\left(\frac{1}{2} \gamma^{33}\left(\omega^{\prime}\right)\left[D_{3}\left(q^{2}\right)\right]^{2}\right.\right. \\
& \left.\left.\quad+\frac{1}{3} \gamma^{88}\left(\omega^{\prime}\right)\left[D_{8}\left(q^{2}\right)\right]^{2}\right) \Gamma\left(1-\alpha_{\rho}(s)\right)\right\} \tag{2.43}
\end{align*}
$$

In evaluating the residue function in (2.43), we use

$$
\begin{equation*}
\omega^{\prime}=1+\frac{s-s_{t}}{a^{2}+q^{2}-s_{t}} \tag{2.44}
\end{equation*}
$$

in the annihilation region.
The scaling variable $\omega$ for annihilation is defined by

$$
\begin{equation*}
\omega=\frac{2 m_{\pi} \nu}{q^{2}}=1+\frac{m_{\pi}^{2}-s}{q^{2}} . \tag{2.45}
\end{equation*}
$$

In the scale invariance limit $q^{2} \rightarrow \infty, \omega$ fixed, we get

$$
\begin{equation*}
\nu \bar{W}_{2}^{\pi}\left(\nu, q^{2}\right) \rightarrow \bar{F}_{2}^{\pi}(\omega)=\left(\frac{-\omega}{2-\omega}\right) F_{2}^{\pi}(2-\omega), \tag{2.46}
\end{equation*}
$$

where $F_{2}^{\pi}$ is given by (2.31). We have used (2.25) to neglect the resonance term $\bar{R}\left(\nu, q^{2}\right)$ in the scale invariance limit $s \rightarrow \infty$.

According to the Callan-Gross relation (2.35), we have

$$
\begin{equation*}
\bar{W}_{1}^{\pi}\left(\nu, q^{2}\right)=\frac{-\nu^{2}}{q^{2}} \bar{W}_{2}^{\pi}\left(\nu, q^{2}\right) \tag{2.47}
\end{equation*}
$$

and

$$
\begin{equation*}
\bar{F}_{1}^{\pi}(\omega)=-\omega \bar{F}_{2}^{\pi}(\omega) \tag{2.48}
\end{equation*}
$$

## 3. Factorization and the pion form factor

Factorization of the Regge residues provides a constraint on the pion structure functions in the Regge region [8] ${ }^{*}$. We assume that the pomeron and $\mathrm{P}^{\prime}$ residues

[^1]for Compton scattering factorize for all values of $q^{2}$ in the limit $s \rightarrow \infty$. Defining the transverse photoabsorption cross section by
\[

$$
\begin{equation*}
\sigma_{\mathrm{T}}\left(s, q^{2}\right)=\frac{4 \pi^{2} \alpha W_{1}^{\pi}\left(\nu, q^{2}\right)}{\nu+q^{2} / 2 m_{\pi}} \tag{3.1}
\end{equation*}
$$

\]

we obtain for the pomeron contribution in the Regge limit,

$$
\begin{equation*}
\sigma_{\mathrm{T}}^{\mathbf{P}}\left(s, q^{2}\right)_{\pi}=\beta_{\mathrm{P}}^{\pi}\left(q^{2}\right) \tag{3.2}
\end{equation*}
$$

Here, $\beta_{\mathrm{P}}^{\pi}\left(q^{2}\right)$ is given by

$$
\begin{align*}
& \beta_{\mathrm{P}}^{\pi}\left(q^{2}\right)=\frac{\pi^{2} \alpha}{m_{\pi}}\left(\left|B_{\mathrm{P}}\right| x_{1} x_{2}\right)^{-1} \mathcal{F}\left(q^{2}, q^{2}\right) \\
& \quad \times\left\{\gamma_{\mathrm{P}}^{33}\left[D_{3}\left(q^{2}\right)\right]^{2}+\frac{1}{3} \gamma_{\mathrm{P}}^{88}\left[D_{8}\left(q^{2}\right)\right]^{2}\right\} . \tag{3.3}
\end{align*}
$$

In the $\gamma \mathrm{p}$ scattering case a similar result is obtained,

$$
\begin{equation*}
\sigma_{\mathrm{T}}^{\mathrm{P}}\left(s, q^{2}\right)_{\mathrm{P}}=\beta_{\mathrm{P}}^{\mathrm{p}}\left(q^{2}\right), \tag{3.4}
\end{equation*}
$$

except that $m_{\pi}$ is replaced by the nucleon mass $M$ and $\gamma_{\mathrm{P}}^{33}$ and $\gamma_{\mathrm{P}}^{88}$ are the residues for nucleon Compton scattering. Factorization means that [8]

$$
\begin{equation*}
\beta_{\mathrm{P}}^{\pi}\left(q^{2}\right)=\frac{\beta_{\mathrm{P}}^{\mathrm{p}}\left(q^{2}\right) \beta_{\mathrm{P}}(\pi \mathrm{~N})}{\beta_{\mathrm{P}}(\mathrm{NN})} \tag{3.5}
\end{equation*}
$$

where $\beta_{\mathrm{P}}(\pi \mathrm{N})$ and $\beta_{\mathrm{P}}(\mathrm{NN})$ are the pomeron residues for $\pi \mathrm{N}$ and NN scattering, respectively. Therefore, we have from (3.3):

$$
\begin{equation*}
\gamma_{\mathrm{P}}^{i i}(\gamma \pi)=\gamma_{\mathrm{P}}^{i i}(\gamma \mathrm{p})\left(\frac{m_{\pi}}{M}\right) \frac{\beta_{\mathrm{P}}(\pi \mathrm{~N})}{\beta_{\mathrm{P}}(\mathrm{NN})}, \quad(i=3,8) \tag{3.6}
\end{equation*}
$$

Similarly, we get for the $\mathrm{P}^{\prime}$ contribution

$$
\begin{align*}
& \frac{1}{2} \gamma_{\mathrm{P}^{\prime}}^{33}(\gamma \pi)=\left[\frac{1}{3} \gamma_{1 \rho}^{33}(\gamma \mathrm{p})+\frac{2}{3} \gamma_{2 \rho}^{33}(\gamma \mathrm{P})\right]\left(\frac{m_{\pi}}{M}\right) \frac{\beta_{\mathrm{P}^{\prime}}(\pi \mathrm{N})}{\beta_{\mathrm{P}^{\prime}}(\mathrm{NN})}, \\
& \gamma_{\mathrm{P}^{\prime}}^{88}(\gamma \pi)=\gamma_{\rho}^{88}(\gamma \mathrm{p})\left(\frac{m_{\pi}}{M}\right) \frac{\beta_{\mathrm{P}^{\prime}}(\pi \mathrm{N})}{\beta_{\mathrm{P}^{\prime}}(\mathrm{NN})} . \tag{3.7}
\end{align*}
$$

The nucleon Compton residues are given in I as [6]:

$$
\begin{align*}
\gamma_{\mathbf{P}}^{33}(\gamma \mathrm{p}) & =0.883 \mathrm{GeV} \\
\gamma_{\mathrm{P}}^{88}(\gamma \mathrm{p}) & =0.357 \mathrm{GeV} \\
\gamma_{1 \rho}^{33}(\gamma \mathrm{p})+2 \gamma_{2 \rho}^{33}(\gamma \mathrm{p}) & =5.12 \mathrm{GeV} \\
\gamma_{\rho}^{88}(\gamma \mathrm{p}) & =0.669 \mathrm{GeV} \tag{3.8}
\end{align*}
$$

and the residues $\beta_{\mathrm{P}, \mathrm{P}^{\prime}}(\pi \mathrm{N})$ and $\beta_{\mathrm{P}, \mathrm{P}^{\prime}}(\mathrm{NN})$ read $[8,10]$

$$
\begin{array}{ll}
\beta_{\mathrm{P}}(\pi \mathrm{~N})=20.1 \mathrm{mb}, & \beta_{\mathrm{P}^{\prime}}(\pi \mathrm{N})=19.8 \mathrm{mb}, \\
\beta_{\mathrm{P}}(\mathrm{NN})=35.6 \mathrm{mb}, & \beta_{\mathrm{P}^{\prime}}(\mathrm{NN})=44.3 \mathrm{mb} . \tag{3.9}
\end{array}
$$

Therefөre, our pion Compton residues are determined to be

$$
\begin{array}{ll}
\gamma_{\mathbf{P}}^{33}=0.074 \mathrm{GeV}, & \gamma_{\mathbf{P}^{\prime}}^{33}=0.228 \mathrm{GeV}, \\
\gamma_{\mathbf{P}}^{88}=0.030 \mathrm{GeV}, & \gamma_{\mathbf{P}^{\prime}}^{88}=0.045 \mathrm{GeV}, \tag{3.10}
\end{array}
$$

and the residues $\gamma_{P}$ and $\gamma_{P^{\prime}}$, defined in (2.34), have the values

$$
\begin{equation*}
\gamma_{P}=0.096, \quad \gamma_{P^{\prime}}=0.13 \tag{3.11}
\end{equation*}
$$

The scale-invariant structure function $F_{2}^{\pi}$ defined in (2.31) is now determined, except for the parameters $A_{\mathrm{P}}, C_{\mathrm{P}}, A_{\mathrm{P}^{\prime}}$ and $C_{\mathrm{P}^{\prime}}$, which control the threshold behaviour of the structure function for $\omega \rightarrow 1$. We have found that $F_{2}^{\pi}(\omega)$ has smooth threshold behaviour if

$$
\begin{array}{ll}
A_{\mathrm{P}}=1.0001, & A_{\mathrm{P}^{\prime}}=1.94, \\
C_{\mathrm{P}}=0.52, & C_{\mathrm{P}^{\prime}}=1.94 . \tag{3.12}
\end{array}
$$

This is shown in fig. 1, where we plot $F_{2}^{\pi}(\omega)$ versus $\omega$.
Having obtained the scale-invariant structure function, we may use the BloomGilman sum rule [7, 8]

$$
\begin{equation*}
\left[F_{\pi}\left(q^{2}\right)\right]^{2}=\int_{1}^{1+\left(W_{\pi}^{2}-m_{\pi}^{2}\right) /\left(-q^{2}\right)} F_{2}^{\pi}(\omega) \mathrm{d} \omega, \tag{3.13}
\end{equation*}
$$

to predict the pion form factor $F_{\pi}\left(q^{2}\right)$. There is some freedom in the choice of the upper limit for the integration in (3.13), although it should not include too much contribution from the higher resonances. With the value $W_{\pi}^{2}=1.7 \mathrm{GeV}^{2}$, we obtain

Fig. 1. The scale-invariant structure function $F_{2}^{\pi}$ for electroproduction is plotted versus $\omega$.

Fig. 2. The pion form factor $F_{\pi}\left(q^{2}\right)$, obtained from the Bloom-Gilman sum rule, is shown as a solid line. The data are taken from ref. [11].
the prediction for the pion form factor shown in fig. 2 along with recent data *. Since (3.13) is not expected to be valid as $-q^{2} \rightarrow 0$ (in fact, it diverges as $-q^{2} \rightarrow 0$ in our model), we show our prediction for $-q^{2} \gtrsim 0.4(\mathrm{GeV} / c)^{2}$. Our model reproduces well both the magnitude and shape of the pion form factor, which lends support to our use of factorization to obtain the scale-invariant pion structure function.

## 4. A sum rule for the multiplicity

In the annihilation region, our model deals with the one-particle inclusive process $\mathrm{e}^{+}+\mathrm{e}^{-} \rightarrow \pi+$ hadrons in the one-photon-exchange approximation. To treat the totally inclusive process $\mathrm{e}^{+}+\mathrm{e}^{-} \rightarrow$ hadrons, we make use of two inclusive sum rules

$$
\begin{equation*}
\iint \frac{\mathrm{d}^{2} \sigma}{\mathrm{~d} \Omega \mathrm{~d} E} \mathrm{~d} \Omega \mathrm{~d} E=\left\langle n_{\pi}\right\rangle \sigma_{\text {tot }}\left(q^{2}\right) \tag{4.1}
\end{equation*}
$$

and

$$
\begin{equation*}
\sum_{c} \iint \frac{\mathrm{~d}^{2} \sigma^{c}}{\mathrm{~d} \Omega \mathrm{~d} E_{c}} E_{c} \mathrm{~d} \Omega \mathrm{~d} E_{c}=\sqrt{q^{2}} \sigma_{\mathrm{tot}}\left(q^{2}\right) \tag{4.2}
\end{equation*}
$$

In (4.1), $\left\langle n_{\pi}\right\rangle$ is the mean multiplicity of the given pion. The sum rule (4.2) is a consequence of energy conservation, and the sum is over all species of hadrons which could be produced in electron-positron collisions. We expect that production of kaons, nucleons, etc., should amount to less than $10 \%$ of the production of pions, so that we may restrict the sum in (4.2) to pions. Furthermore, in our model the $\pi^{+}$, $\pi^{-}$and $\pi^{\mathrm{o}}$ production cross sections are equal, so that (4.2) may be written

$$
\begin{equation*}
3 \iint \frac{\mathrm{~d}^{2} \sigma}{\mathrm{~d} \Omega \mathrm{~d} E} E \mathrm{~d} \Omega \mathrm{~d} E=\sqrt{q^{2}} \sigma_{\mathrm{tot}}\left(q^{2}\right) \tag{4.3}
\end{equation*}
$$

The mean multiplicity is then obtained by combining (4.1) and (4.3):

$$
\begin{equation*}
\left\langle n_{\pi}\right\rangle=\frac{\sqrt{q^{2}} \iint \frac{\mathrm{~d}^{2} \sigma}{\mathrm{~d} \Omega \mathrm{~d} E} \mathrm{~d} \Omega \mathrm{~d} E}{3 \iint \frac{\mathrm{~d}^{2} \sigma}{\mathrm{~d} \Omega \mathrm{~d} E} E \mathrm{~d} \Omega \mathrm{~d} E} . \tag{4.4}
\end{equation*}
$$

In the scale-invariant limit $q^{2} \rightarrow \infty$, we get

$$
\begin{equation*}
\left\langle n_{\pi}\right\rangle=\frac{2}{3} \frac{\int_{2 m_{\pi} / \sqrt{q^{2}}}^{1} \omega \bar{F}_{1}(\omega) \mathrm{d} \omega}{\int_{2 m_{\pi} / \sqrt{q^{2}}}^{1} \omega^{2} \bar{F}_{1}(\omega) \mathrm{d} \omega} \tag{4.5}
\end{equation*}
$$

[^2]
## 5. Results for $\mathrm{e}^{+} \mathrm{e}^{-}$annihilation

The recent experimental results obtained by the SLAC-LBL-SPEAR group [2], have certain remarkable features. The inclusive differential cross section $E_{\pi} \mathrm{d}^{3} \sigma / \mathrm{d}^{3} p_{\pi}$ is similar to an analogous distribution for $\mathrm{pp} \rightarrow \pi \mathrm{X}$ at $90^{\circ}$ observed at NAL [12] ${ }^{*}$. Measurements of $\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons $)$ in the range 16 to $25 \mathrm{GeV}^{2}$, which have been made at CEA and SLAC, are consistent with a constant or slowly falling cross section in this range of $q^{2}$. Morcover, the ratio $R=\sigma\left(\mathrm{c}^{+} \mathrm{c}^{-} \rightarrow\right.$ hadrons $) / \sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mu^{+} \mu^{-}\right)$ conflicts with the predictions of the parton model, current algebra and asymptotically free non-Abelian gauge theories.

It has been suggested [13] that there may exist a lepton-hadron interaction which produces these unexpected results, but such a suggestion may conflict with quantum electrodynamics.

We shall explain the SLAC results in our model by observing that the missing mass channel resonances ( $\rho, \omega, \phi$, etc. . .) build up in a "statistical bootstrap" way to give a diffractive-type of scattering similar to that found in hadronic pp collisions. The mechanism for this is already contained in our model in the term $\bar{R}\left(\nu, q^{2}\right)$, in eqs. (2.39) and (2.43), which was taken to be negligible in our previous work [6] on $\mathrm{c}^{+}+\mathrm{e}^{-} \rightarrow \overline{\mathrm{p}}+\mathrm{X}$, due to the meagre production of baryon resonances in the missing mass channel (this latter assumption is, of course, subject to experimental verification).

To treat $\sigma_{\text {tot }}$ and $\left\langle n_{\pi}\right\rangle$, we employ the sum rules (4.1) and (4.3). From the Cal-lan-Gross relation (2.47), we see that the inclusive cross section (2.36) depends only on $\nu \bar{W}_{2}\left(\nu, q^{2}\right)$. Our model for $\nu \bar{W}_{2}\left(\nu, q^{2}\right)$ is given by (2.39), with $\nu \bar{W}_{2}^{\mathrm{P}}, \nu \bar{W}_{2}^{\mathrm{P}^{\prime}}$ and $\bar{R}$ given by (2.28), (2.29) and (2.43), respectively. The terms $\nu \bar{W}_{2}^{\mathrm{P}}$ and $\nu \bar{W}_{2}^{\mathrm{P}^{\prime}}$ have been fixed by the discussion of sect. 3, so that only $\bar{R}$ may be varied to fit $\sigma_{\text {tot }}$ and $\left\langle n_{\pi}\right\rangle$.

We choose $\Lambda$ and $\Delta$ large, so that the factor involving $\Lambda$ and $m$ in (2.22) may be replaced by 1 at moderate values of $s$. Then $\bar{R}$ is fixed by choosing values for $n, k$, $g_{1}$ and $g_{2}$ in (2.22) and (2.23). The parameter $k$ sets the normalization of the cross section, $n$ controls the energy dependence of the cross section through (2.26), and $g_{1}$ and $g_{2}$ are important for the $\omega$-dependence of $\nu \bar{W}_{2}$, and hence, via (4.4), for the multiplicity. Only by simultaneously fitting both $\sigma_{\text {tot }}$ and $\left\langle n_{\pi}\right\rangle$ can $n, k, g_{1}$ and $g_{2}$ all be determined.

By choosing $n=\frac{1}{2}, k=1.68 \times 10^{6}, g_{1}=13.0$ and $g_{2}=0.1$, we obtain $\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons) shown in fig. 3 and compare it with the world's data [14]. In fig. 4 we compare our result for $R=\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons $) / \sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mu^{+} \mu^{-}\right)$with the CEA and Frascati data. Since $\omega^{\prime} \rightarrow \omega$ in the scale invariance limit, we see that scale invariance of $\bar{R}$ is broken by the factor involving $\Lambda$ and $m$ in (2.22), and by the factor $\sqrt{q^{2}}$ coming from (2.26) when $n=\frac{1}{2}$. Hence, the ratio $R$ will rise linearly versus $\sqrt{q^{2}}$ until $q^{2}$ is of the order of either $\Lambda$ or $\Delta \rho$ (the parameter which determines the asymptotic regime of the $\rho$ trajectory [6]), whichever is smaller. Since $m$ is large $\bar{R}$ will

[^3]

Fig. 3. Our fit to the cross section $\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons) (solid line) as a function of $\sqrt{q^{2}}$ is compared with the world's data, quoted in ref. [14].

Fig. 4. The resulting ratio $R=\sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow\right.$ hadrons $) / \sigma\left(\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \mu^{+} \mu^{-}\right)$is displayed as a solid line against the data. Note the linear increase in $\sqrt{q^{2}}$.

Fig. 5. Our fit to the multiplicity $\left\langle n_{c}\right\rangle$ for the production of charged pions, plotted against $\sqrt{q^{2}}$ and compared with the data (refs. [1,15]).

Fig. 6. The predicted angular distribution $\mathrm{d} \sigma / \mathrm{d} \Omega$ versus $\theta$ for $\sqrt{q^{2}}=4.8$ and 10 GeV .

Fig. 7. The predicted $q^{2} \mathrm{~d} \sigma / \mathrm{d} x$ for $\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \pi^{\mathrm{c}}+$ hadrons plotted versus $x=2 E / \sqrt{q^{2}}$ for $\sqrt{q^{2}}=3.0,3.8,4.8$ and $10 \mathrm{GeV}_{,}$and showing a marked breaking of scaling for $x \leqslant 0.5$. The dashed part of the curve for $\sqrt{q^{2}}=3.0 \mathrm{GeV}$ corresponds to $s<5 \mathrm{GeV}^{2}$.
vanish as $q^{2} \rightarrow \infty$, and $R$ will eventually tend to the value $1.45 \times 10^{-3}$, given by the scale-invariant $\mathbf{P}$ and $\mathbf{P}^{\prime}$ terms. The $\mathbf{P}$ and $\mathbf{P}^{\prime}$ terms become scale-invariant at relatively low values of $q^{2}$; for example, at $q^{2}=25 \mathrm{GeV}^{2}$ they contribute $0.03 \%$ to $R=5.89$.

Our fit to the multiplicity $\left\langle n_{\mathrm{c}}\right\rangle$ for the production of charged pions is shown in fig. 5 and compared with CEA and Frascati data $[1,15]$. The multiplicity is predicted to rise slowly versus $\sqrt{q^{2}}$ and then tend to the value 2.26 given by (4.5) as $\sqrt{q^{2}} \rightarrow \infty$. We observe from eq. (4.4) that this prediction depends only on the shape of the structure functions. We also note that the asymptotic values $\left\langle n_{\mathrm{c}}\right\rangle=2.26$ and $R=1.45 \times 10^{-3}$ constitute predictions determined by the discussion of sect. 3, and completely independent of the form $\bar{R}$.

Having fixed the parameters in our model, we can now examine the inclusive cross section. In fig. 6 , we display the predicted angular distribution $\mathrm{d} \sigma / \mathrm{d} \Omega$ and we see that it is fairly flat between $45^{\circ}$ and $135^{\circ}$. By integrating the cross section $q^{2} \mathrm{~d}^{2} \sigma^{\pi /} / \mathrm{d} \Omega \mathrm{d} x$ for the inclusive reaction $\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \pi^{-} \mathrm{X}$ over all angles we obtain the

Fig. 8. Our prediction for $E \mathrm{~d}^{3} \sigma / \mathrm{dp}^{3}$ at $90^{\circ}$ for $\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \pi^{-}+$hadrons, plotted on a logarithmic scale versus $p$ at $\sqrt{q^{2}}=3.0,3.8,4.8$ and 10 GeV .
predictions shown in fig. 7, plotted versus $x=2 E / \sqrt{q^{2}}$ for $\sqrt{q^{2}}=3.0,3.8,4.8$ and 10 GeV . We see that there is a marked breaking of scaling in fig. 7 for $x \leqslant 0.5$.

In fig. 8, we show our results for $E_{\pi} \mathrm{d}^{3} \sigma / \mathrm{d} p^{3}$. The predicted slope is approximately the same at $90^{\circ}$ as in the process $\mathrm{pp} \rightarrow \pi^{-} \mathrm{X}$ measured at NAL [12] when $\sqrt{q^{2}}=4.8 \mathrm{GeV}$.

Finally, in fig. 9 , we display the predicted annihilation structure function $2 m_{\pi} \bar{W}_{1}^{\pi}$, plotted versus $\omega$ for $\sqrt{q^{2}}=4.8$ and 10 GeV . Again we observe the strong scale-breaking effects around $\omega \sim 0.2$.

It should be mentioned at this point that we do not expect our small $q^{2}$ predictions to be accurate, because we have not, as yet, treated the resonance pole contributions correctly for $q^{2} \lesssim 5 \mathrm{GeV}^{2}$.

If the QED inequality [9]

$$
\begin{equation*}
\frac{\alpha}{3 \pi} \int \frac{R\left(q^{2}\right)}{q^{2}} \mathrm{~d} q^{2}<1 \tag{5.1}
\end{equation*}
$$

Fig. 9. Predicted annihilation structure function $2 m_{\pi} \bar{W}_{1}$ plotted versus $\omega$ for $\sqrt{q^{2}}=4.8$ and 10 GeV . Note the strong scale-breaking around $\omega=0.2$.
is to hold, we find that the behaviour of $R$ predicted in fig. 4 may continue up to $\sqrt{q^{2}} \approx 550 \mathrm{GeV}$. As discussed above, the extent to which this behaviour may continue is controlled by the parameters $\Lambda$ and $\Delta \rho$, and without a knowledge of their values we cannot say whether the bound (5.1) is satisfied or violated in our model.

It is important to recognize that all our results are based on the one-photon exchange approximation.

## 6. Discussion of results

From our unified description of current-hadronic processes in I and II and in the present work, we have succeeded in fitting a remarkable amount of data. Our results for $\mathrm{e}^{+} \mathrm{e}^{-} \rightarrow \pi \mathrm{X}$ are consistent with the CEA-SLAC data and have their origin in a simple physical mechanism, namely, the build-up of resonances in the multi-pion missing mass channel. One can only expect to get detailed predictions, as we have obtained, from a model which contains a great deal of information about the dynamics of the interactions; such a model can be found by using $S$-matrix methods based on
well-founded physical properties, such as analyticity, crossing symmetry, Regge behaviour, vector-meson dominance, etc. It is too early to say what connection, if any, a physical description of this kind has with the constituent picture of the hadrons.

We thank Dr. I.O. Moen for a helpful and stimulating discussion.

[^1]:    * It should be noted that if we perform a Mellin transform of the pomeron amplitude term in (2.12) then, due to the logarithmic factor, the leading singularity in the angular momentum plane will be a dipole $\approx 1 /(J-\alpha(t))^{2}$, so that factorization of the pomeron is not strictly valid. But we shall assume, nevertheless, that we can factorize the pomeron residue.
